Further Observations on the Political Business Cycle in German Monetary Aggregates

Helge Berger
Ulrich Woitek*

CES, University of Munich and University of Glasgow

February 1999

Abstract
Arguably, Germany has the world's most independent central bank. Surprisingly, however, recent work has found political business cycles in German monetary aggregates. It is hard to explain this with standard models of opportunistic government behavior. Instead we show that the cycles originate from shifts in money demand tolerated by the Bundesbank. Such shifts occur because, when inflation preferences differ between political parties and election results are uncertain, rational investors avoid entering long term financial contracts before elections. Contrary to the Bundesbank's stated commitment to a monetaristic policy rule, it appears to allow these changes to have an impact on monetary aggregates.

1. Introduction

There is a paradox in the literature on central banking. While it is generally believed that central bank independence is a means of preventing opportunistic Nordhaus-type monetary policy around elections, there is strong evidence that the German Bundesbank – repeatedly found to be “one of the most independent central banks of the world” (Eijffinger and De Haan (1996), Cukierman (1996)) and the European Central Bank’s role model – has tolerated a political business cycle in German monetary aggregates.\(^1\) Results to that end were first reported by Alesina, Cohen, and Roubini (1992) and later confirmed by Berger and Woitek (1997a). Both groups of authors found an increase in the growth rates of various German monetary aggregates before elections and a matching decline afterwards. The cycle is small in quantitative terms (+/– 0.2 to 0.4 percentage points) but extremely strong statistically. The result is robust with respect to the specific (real or nominal) monetary aggregate analyzed, the univariate or multivariate specification of the estimated time series model, alternative data frequencies, and different methods of modeling seasonality.\(^2\) Including or excluding the turmoils of German unification after 1989 in the analysis also does not change the outcome.

There are two possible explanations for this discrepancy between the Bundesbank’s reputation and the occurrence of a political business cycle in German money. One is that it is not a contradiction in the first place, but rather a consequence of the interaction between the Bundesbank and the German government. If the Bundesbank Council had partisan preferences, it might in fact (mis-) use its independence to either support or fight an incumbent government depending on the ideological beliefs of the Council’s median voter (Vaubel (1997a), Sieg (1997)). If the partisan beliefs of the two actors coincide (do not coincide) before an election, the bank will follow an expansionary (a contractionary) monetary policy stance which it will then correct after the event. In other words, the opportunistic cycle might be an anomaly in the data. Obviously this hypothesis can only be tested if the partisan preferences of the

---

\(^1\) For the theory of opportunistic political business cycles see Nordhaus (1975) and Rogoff and Sibert (1988). The literature is surveyed in Nordhaus (1989).

\(^2\) Additional variables introduced include a proxy for the world business cycle (Alesina, Cohen, and Roubini (1992)), the balance-of-payments and the exchange rate (Berger and Woitek (1997a)). See Lang and Welzel (1992) for a critical view.
Bundesbank can (at least *ex post*) be exposed by a knowledgeable researcher. Assuming the party preferences of a Council member to be identical with those of the government body that nominated the individual, Vaubel (1993, 1997a) was unable to refute the hypothesis. However, his results were questioned by Berger and Woitek (1997b) using data on the individual voting behavior of the Bundesbank Council.³

There is, however, an alternative explanation for the coexistence of central bank independence and political business cycles in German monetary aggregates. If the Bundesbank were as devoted a supporter of monetarist principles as it claims to have been since the mid-1970s, the conclusion that it actively steers monetary policy in an opportunistic fashion around elections could hardly be avoided. On the other hand, the Bundesbank might instead follow an interest-rate policy aimed at stabilizing the economy around presumed long-run equilibrium values of key variables in its target function such as inflation and real activity (Taylor (1993a, 1993b)). As a matter of fact, a number of recent econometric results point in the latter direction (Bernanke and Mihov (1996), Clarida and Gertler (1997), Clarida, Galf, and Gertler (1997)).

Section 2 of the paper will extend the existing literature by providing results based on the Bundesbank’s performance since the early 1950s. If the outcomes mentioned can be supported, the Bundesbank’s money supply should indeed be viewed as highly elastic (in the short run) and it will be shifts in money demand rather than money supply that determine the volume of monetary aggregates. But in that case, why should money demand be influenced by politics?

The answer may lie in the uncertainty created by upcoming elections. Alesina and Rosenthal (1995) argue that politicians have partisan preferences which are distinct enough to introduce permanent differences in the way they conduct fiscal policy or try to influence monetary policy.⁴ If this is correct (or at least could not be ruled out by perfectly rational observers),

---

³ The fact that both Alesina, Cohen, and Roubini (1992) and Berger and Woitek (1997a) find significant straightforward political business cycles in the data on monetary aggregates already suggests that the partisan preference hypothesis is empirically hard to distinguish from the simple opportunistic case. See, however, Vaubel (1997b).

⁴ Alesina, Cohen, and Roubini (1992) find support for a variant of this hypothesis that focuses on actual government changes in German and international data. Berger and Woitek (1997a) differ in their results but point to the fact that the relative stability of Germany’s political history severely restricts the number of relevant observations. Note that the absence of frequent actual government changes *ex post* does not invalidate our argument concerning expectations.
interest rate forecasts extending into post-election periods will depend on a weighted average of the inflation rates expected for all possible election results. To avoid this uncertainty, financial investors might find it beneficial to postpone certain commitments. They will trade longer term assets for shorter term assets and thus - with a highly elastic money supply - enlarge monetary aggregates as defined, for instance, in M3, M2 or M1. Since the policy stance of the new government is known for sure after the election, the process will be reversed at this time. For an uninformed outside observer, however, the phenomenon, which is really a demand-induced pattern caused by the uncertainty connected with elections and, possibly, partisan politics, might look like a Nordhaus or Rogoff/Sibert type opportunistic political business cycle. Consequently, Section 3 provides tests for the impact of elections on money demand. Section 4 contains our conclusions.

2. Bundesbank Policy
2.1 A Standard Reaction Function

Is the political business cycle in German monetary aggregates 1950-96 the doing of the Bundesbank? To answer this question, we extend the standard reaction function approach to monetary policy.\footnote{See for a similar approach, among others, Bernanke and Mihov (1996), Clarida and Gertler (1997), and Clarida, Gali and Gertler (1997). A critical examination is in Solveen (1998).} We look at the following model for $i_t$, the day-to-day or short-term interest rate that is tightly controlled by the Bundesbank:

$$
    i_t = \lambda i_t^0 + (1 - \lambda) \sum_{i=1}^{k} \omega_i i_{t-i} + \delta D_{t}^{pol} + \epsilon_t,
$$

To capture both the potential economic and political targets the Bundesbank might follow, $i_t$ is a weighted average of $i_t^0$, the Bundesbank’s target for the day-to-day rate and a weighted sum of past interest rates ($\sum_{i=1}^{k} w_i = 1$) to allow for partial adjustment over time.\footnote{Woodford (1998) argues that a certain degree of policy inertia is optimal.} The dummy variable $D_{t}^{pol}$ captures political influences, and $\epsilon_t$ is a white-noise random variable capturing the bank’s stochastic control problems. We assume that $i_t^0$ is given by
\[ i_t = E_t \left[ \tilde{\pi}_{t+k_1} \right] + r_t^* + \gamma^* (E_t \left[ \tilde{\pi}_{t+k_1} \right] - \tilde{\pi}^*) + \gamma^*(E_t \left[ \tilde{y}_{t+k_2} \right] - \tilde{y}^*) + \gamma^*(E_t \left[ \tilde{m}_{t+k_1} \right] - \tilde{m}^*) \]  

(2)

where \( E_t \) is a \( k_i \) (\( i=1,2,3 \)) period forward looking expectations operator conditioned on the information available to the Bundesbank in period \( t \). The \( k_i \) represent the lags the Bundesbank anticipates for monetary policy to influence its target variables. \( r_t^* \) is the central bank’s target rate rate of \( r_t \), the real short term interest rate. \( \tilde{\pi}_{t+k_1} \) \( (\tilde{m}_{t+k_1}) \) is the inflation rate (the growth rate of the real money stock) in \( t+k_1 \) \( (t+k_3) \) and \( \tilde{\pi}^* \) \( (\tilde{m}^*) \) is the target rate of inflation (growth rate of the money stock). \( \tilde{y}_{t+k_2} \) and \( \tilde{y}^* \) are the growth rate of real output in \( t+k_2 \) and its target rate, respectively.

The reaction function specified in (1) and (2) implies that, as far as its economic targets are concerned, in the long run, the Bundesbank aims at a certain target real day-to-day interest rate (note that the right hand side includes the term \( E_t \left[ \tilde{\pi}_{t+k_1} \right] \) with a coefficient restricted to 1). In the short run, the Bundesbank reacts to inflationary pressures whenever the expected inflation rate is higher than target inflation, or whenever output rises over its targeted value. If the bank conducts its policy “benevolently”, the political influences captured in \( D_{t}^{\text{pol}} \) will play no role in the determination of \( i_t \) in addition to the economic policy targets, i.e., \( \delta \) will be 0.

Two issues, one technical and one institutional, demand our attention before we can turn to the empirical investigation of Bundesbank behavior. The first issue concerns the computation of the RHS variables, i.e., of the target levels and of expected inflation, output and real money growth. We assume that, with the possible exception of the monetary goal, the Bundesbank targeted the long run equilibrium values of the RHS variables. Again following standard methods, we compute the long run equilibrium values, expected inflation, output and money growth as well as the lag-structure \( (k_i) \) in equation (2) from a structural VAR model described in Appendix 1 (cf. Clarida and Gertler (1997)).

The second issue arises, because in order to maximize the number of observations on elections, we extend the sample of the empirical exercise to include the Bretton Woods period 1950-73. The empirical literature on German monetary policy, as a rule, excludes the 1950s and 1960s
from its analysis. This is, however, an unnecessary, and possibly also misleading, limit to the
data set. As argued by Berger (1997), the Bundesbank\(^7\) between 1950 and 1973 was very
similar to today's conservative and independent institution. Of course, simply including the
1960s, the "hard period" of the Bretton Woods system (Obstfeld (1993)) in the VAR model
and, thus, in the estimation of the Bundesbank reaction function described in (1) and (2), could
also be a mistake. While during the "soft period" of Bretton Woods in the 1950s the D-Mark
was not convertible and the Bundesbank was essentially unrestricted by the exchange rate
system, it faced a sometimes binding policy constraint from January 1959, when currency
markets were fully liberalized, to March 1973, when the system was finally dissolved.

To control for the effects of the fixed exchange rate regime, we extent the VAR model used to
compute the RHS variables for the estimation of the Bundesbank reaction function. For the
duration of the "hard" Bretton Woods system, we introduce two additional exogenous
variables to the model described in Appendix 1: the U.S. Federal Funds Rate and the nominal
D-Mark/Dollar exchange rate. The former variable is an indicator for the monetary policy
conducted by the dominant central bank under the fixed exchange rate system, the U.S. Federal
Reserve. As expected, the federal funds rate has a significant and positive effect on the day-to-
day rate during this period. This also holds for the second variable. The reason is that nominal
appreciations of the D-Mark, for instance in 1961, 1969, and 1971, gave the Bundesbank some
leeway to raising its own interest rate. It turns out that the forecasts and long-run equilibria of
the VAR model are rather robust to the introduction of controls for the fixed exchange rate
regime and that This is also true for a number of alternative types of controls.\(^8\)

---

\(^7\) Before 1957 the German central bank was named *Bank deutscher Länder*.

\(^8\) For instance, we get strikingly similar results, if instead we estimate the structural VAR for different
subperiods, allowing it to adapt to the particularities of the "soft" Bretton Woods period up to the end of 1958,
the "hard" Bretton Woods period up to March 1973, when the system was finally dissolved, and the post-
Bretton Woods era thereafter. The subperiods can also be justified by statistical tests on structural breaks. We
allow the lag length of the VAR part of the model to differ between the subperiods and introduce a time trend
when appropriate. Around the regime changes (1959:1 and 1973:4), we assume that the Bundesbank relies on
the forecasts made with the help of the previous model until the available number of observations allows the
new model to be used. Using the forecasts taken from the previous model as starting points for the new model
does not change the results much. Details available on request.
2.2 Results for the Reaction Function

Building upon Section 2.1, we estimated the following empirical model of the reaction function of the Bundesbank (see equations (1) and (2)):

\[ i_t = c + a_1 (\hat{\pi}^h_t - \hat{\pi}^*_{t-h}) + a_2 (\hat{y}^h_t - \hat{y}^*_{t-h}) + a_3 mt_t + a_4 D^\text{pol} + \sum_{j=1}^{3} b_j i_{t-j} + u_t , \] (6)

where \( c \) is a constant, \( \hat{\pi}^h_t - \hat{\pi}^*_{t-h} \) and \( \hat{y}^h_t - \hat{y}^*_{t-h} \) are the deviations of the predicted inflation rate and production growth from their long run equilibrium values, \( h \) is the forecast horizon, \( mt_t \) is the deviation from the monetary target, and \( D^\text{pol} \) is the election dummy.

Table 1 presents the long run equilibrium or steady state values stemming from the VAR model described above and compares them to the means of the respective time series'.

(\text{Table 1 about here})

In the case of \( mt_r \), we will consider deviations from the politically defined Bundesbank policy targets in addition to deviations from the long run equilibrium value.\(^9\) As to the policy lags, we choose \( h = 6 \) for production and inflation, and \( h = 12 \) for the monetary aggregate.\(^10\) The political variables fall into two cases: (1) the dummy \( D^\text{pol} \) covers the pre-election period, and (2) \( D^\text{pol} \) covers the post-election period. Three different lags for the pre- and the post-election dummies are used, covering the periods 18 months (pre-election: \( D_3 \); post-election: \( D_3 \)), 12 months (pre-election: \( D_2 \); post-election: \( D_2 \)), and 6 months (pre-election: \( D_1 \); post-election: \( D_1 \)). A new model is estimated for every political variable. While the time structure of the dummy variables remains simple, it is flexible enough to capture attempts of the Bundesbank to

\(^9\) Note that our approach assumes that the Bundesbank formulates its policy targets in real terms and that the early policy targets were formulated for base money not for M3. It turns out, however, that using nominal instead of real M3 and keeping track of the changing definitions of the aggregates targeted by the Bundesbank, has no influence on the results. Therefore, for the sake of consistency, we restrict ourselves to the findings based on real M3.

\(^10\) See Appendix 1 for a discussion of the policy lags in the VAR model. Taking into account the instruments (see Tables 2), the actual lags estimated become 8 and 14 periods, respectively.
increase M3 prior to elections and to decrease it after them. For the AR-part of the above equation, lag 5 is chosen in order to deal with the autocorrelation in the residuals.

Table 2 contains the results for the reaction function with the monetary target as defined in equation (2) as well the outcomes with the monetary targets as announced by the Bundesbank. Since the Bundesbank did not formulate explicit policy targets for the growth rate of monetary aggregates before 1975, the observation period in latter case is only 1975:01-1996:05 while in the former case it is 1950:01-1996:05.

We first discuss the results for the monetary target defined as the long run equilibrium value (part (i) of Table 2). We find that both inflation and the production gap have the correct signs and are (with exceptions for real activity) significant at conventional levels. Somewhat surprisingly, however, the deviations of the monetary growth rate from its long run equilibrium value seem to be without conventionally significant influence on the Bundesbank’s decisions.

One way to interpret this outcome is that, despite its rhetorical commitment to a Friedman-type policy rule, the German central bank has followed an interest rate rule that rendered money supply almost perfectly elastic. As to the political variables, part (i) of Table 2 shows that the election dummies, too, lack a convincing impact on the Bundesbank’s policy. The only dummy variable significant at least at a 5 percent level is $D_1$, which is active in the six months after the election. This may be interpreted as a sign that the Bundesbank sometimes postpones an increase in the of its interest rate until immediately after elections. There is, however, no sign of a systematic decline of short-term interest rates before the election – something we

---

11 We also estimated a model for the period 1973:3 to 1989:11 to make sure that the effects of German re-unification do not significantly alter our results, which is not the case.

12 Since $a_1$, which theoretically is defined as $1 + \gamma^2$, is strictly smaller than 1, we have to conclude that the Bundesbank does allow the real interest rate to deviate from its target value. See equation (2). Clarida and Gertler (1997) have a similar result for their period of observation.

13 This is in line with the results in Bernanke and Mihov (1996).

14 The result is robust across alternative forecast rules. For instance, a similar pattern can be found following the so-called Taylor rule.
would expect if the Bundesbank deliberately creates political business cycles in German monetary aggregates. As we will see in Section 3, the last two results have important consequences for the explanation of the political business cycles found in German monetary data. Before we turn to these consequences, however, we should consider a counter-argument concerning the Bundesbank’s monetary target procedure.

As already mentioned, the Bundesbank did not formulate explicit policy targets for the growth rate of monetary aggregates before 1975. Inasmuch as these explicit targets defined a factual policy change and deviated from the long-run equilibrium values used for the results presented in section (i) of Table 2, the model may be biased in favor of a rejection of the Friedman rule. To test this counter argument, we estimate a second set of reaction functions that takes account of the Bundesbank’s explicit policy targets. Since the Bundesbank usually sets a upper and a lower bound for its target rate rather than a single number, we allow for two alternative interpretations of the policy target: the mean of the two bounds (part (ii) of Table 2) and deviations from the upper and lower bound (part (iii)). However, the parameters for deviations from the monetary targets are not significant. Again the Bundesbank seems to follow an interest rate rule focusing on inflation and real economic activity rather than monetary aggregates, and, once more, there is no evidence that the Bundesbank reacts to elections in the way predicted by political business-cycle models.

3. Money Demand and Elections

Since we have rejected the notion that the Bundesbank actively creates the political business cycle in monetary aggregates, these regularities must have another source. In this Section we put forward the hypothesis that the cycles originate from shifts in money demand that are tolerated by the Bundesbank, because – as we have just shown – the bank follows an interest rate policy rule. We argue that changes in money demand prior to elections occur because, when political parties have different inflation preferences and election results are uncertain, rational investors avoid entering long term financial contracts before elections (see e.g. Alesina and Rosenthal (1995)).
To understand how the effect might work for money demand, consider a simple portfolio model, where real demand in every time period depends positively on the output level, negatively on the ratio of long and short term interest rates, and positively on a pre-election dummy $D_{1}^{pol}$.

$$M^{D} = M^{D}(y, \frac{i^{L}}{i}, D_{1}^{pol}) .$$

(7)

The long-term interest rate ($i^{L}$) is an indicator of the opportunity costs of holding real money ($M$), i.e., the yields resulting from holding the alternative long-term asset ($B$). The short-term rate reflects the fact that broad monetary aggregates such as M3 encompass assets which yield a positive return. This return can be approximated by the money-market rate. Total wealth is $V = M+B$.

(Figure 1 about here)

In Figure 1, $M$ ($B$) is measured from the left (right). The negative slope of $M^{D}$ is due to the fact that, everything else being equal, individuals want to increase their money holdings by selling bonds to the central bank as $i^{L}$ decreases and $i$ increases. For a given money supply $M_{0}$, the interest-rate ratio $(i^{L}/i)_{0}$ clears both the money and the bond markets and point A is an equilibrium. Now, assume that $\Delta D_{1}^{pol} > 0$ before an election. As mentioned above, the prospect of an election will increase the uncertainty in bond yields faced by investors.\(^{15}\) Hibbs (1977), Alesina (1988, 1989), and Alesina and Rosenthal (1995) argue that politicians differ in their partisan preferences for inflation. Since these differences might suffice to introduce permanent differences in the way fiscal policy is conducted or the extent to which a conservative monetary policy will go unchallenged, interest rate forecasts extending into post-

\(^{15}\) We assume investors who think about buying another one year bond to replace for a similar bond in their portfolio less than one year before an election. Election uncertainty will cause other substitution effects as well. For instance, investors will avoid four year bonds three years before an election, three year bonds two years before an election, and so forth.
election periods will depend on a weighted average of the inflation rates expected for all possible election results. To avoid this uncertainty, investors will want to go “short”, that is, they will try to sell bonds to the central bank for money. In the context of Figure 2, $\Delta D^{pol} > 0$ will cause $M^D$ to shift to the right ($M^{D+}$): for any given interest-rate ratio, real money demand will be higher than before. In line with the empirical evidence introduced above, we can safely assume the money supply to be perfectly elastic with respect to $i$ and unaffected by the upcoming election. If money supply in addition would also be able to satisfy the increased demand for money without delay, i.e. expand the stock by the difference $M_0-M_1$, we would immediately jump from point A to the new equilibrium at point C in Figure 2. The interest rates would remain unchanged. To see what would happen if, instead, the adjustment process takes some time, assume that $M$ is constant. The shift in money demand would then cause $(i^L/i)$ to rise to $(i^L/i)_1$ to clear markets at point B. At the same time, as money supply partially adjusts to increased demand, a point like E, were $M>M_0$ and $(i^L/i)<(i^L/i)_1$, would be reached instead. So what we should observe with non-immediate adjustment in pre-election periods is a positive correlation between the interest rate ratio and $M$. The result guarantees that our explanation of the political business cycle in German monetary aggregates can be empirically tested. While we should observe a negative relation between the interest rate ratio and $M$ as predicted by standard money demand theory in non-election periods, we ought to observe a positive correlation in pre-election periods. This is also true for the opposite movement from a point like C to F, when $\Delta D^{pol}_1<0$ after the election. When money supply adjusts only gradually, the shift back to $M^D$ will cause both the interest-rate ratio and $M$ to decrease.

A necessary condition for the hypothesis of a demand-induced political business cycle in German monetary aggregates to be true is that, on average, $(i^L/i)$ rises before elections and falls after elections. To see whether this condition is fulfilled, Table 3 presents the results for a set of election dummies in a simple regression of the form

---

16 $i^L$ is the (volume weighted) average monthly long term rate of return on bonds with fixed nominal interest rates and an average remaining term length of at least 3 years. The series is published by the Bundesbank under the code WU0017. 1950:01 to 1958:12 supplemented with data computed from the Bundesbank’s Monthly Reports (various issues). Details available from the authors.
\[ \frac{i_t^L}{i_t} = c + \sum_{j=1}^{3} b_j \frac{i_{t-j}^L}{i_{t-j}} + \alpha D_{jt}^{pol} + \epsilon_t \]  

(8)

The dummy variable \( D_{jt}^{pol} \) is active in the 6/12/18 months before \( (j=1) \) and 6/12/18 months after \( (j=2) \) the election month. Again we use monthly data for the period 1951:01 to 1996:05. Obviously the interest rate ratio exhibits the presumed characteristics. There is a significant increase before an election and a fall after the election. Note, however, that the strength of the effect of electoral uncertainty is not perfectly symmetric. For instance, the interest rate ratio increases by almost 0.5 percentage points in the 18 months prior to the election, but decreases only by about 0.3 percentage points in the 18 months thereafter. We obtain similar results for annual changes of the ratio.\(^{17}\)

(Table 3 about here)

Before we estimate equation (6) for money demand, we consider the issue the issue of seasonal integration (Berger and Woitek (1995)). As the HEGY-test\(^{18}\) for the variables of interest suggests, there is integration at seasonal frequencies. Given this result, we allow for seasonal cointegration relationships as well. Therefore, we used the following error correction model:

\[ \hat{m}_t = c + \sum_{j=1}^{p} d_j \hat{y}_{t-j} + (a_1 + a_2 D_{jt}^{pol})(1 - B^{12}) \frac{i_t^L}{i_t} + \sum_{j=1}^{p} b_j \hat{m}_{t-j} + \sum_{j=1}^{7} \gamma_j ecm_{j,t-1} + \epsilon_t \]  

(9)

The growth rate of (real) M3 is denoted by \( \hat{m}_t \), \( \hat{y}_t \) is the output growth rate, and \( i_t^L \) is the long term interest rate. \( B \) denotes the backshift operator. The variables \( ecm_j, j = 1,..7 \) are the

\(^{17}\) The results are available on request.

\(^{18}\) Hylleberg, Engle, Granger, and Yoo (1990). Detailed results are available on request.
residuals from the cointegration equations at each of the relevant seasonal frequencies.\textsuperscript{19} The exact lag structure for the short run dynamics is determined by standard t-statistics. We chose lag 1 for $\hat{y}_t$ and lags 1 and 3 for $\hat{m}_t$, but the results are fairly robust with regard to the lag length used. The observation period is again 1951:01 to 1996:06.

The portfolio model described above does suggest a joint test of the correlation between money demand and the interest rate ratio in the pre- and post-election periods. Therefore Table 4 presents the results for three alternative variables, $D_{t}^{pol} = DI, DII, DIII$, which are 1 in the 18, 12, and 6 months before and after the election month and 0 otherwise. The parameter $a_1$ should be negative, i.e. if there is an increase in $i^L_t / i_t$, there will be a portfolio shift from money to bonds. If our model is correct, $a_2$ should be positive and larger than $a_1$ for the election effect to have an overall positive impact on money demand.

\begin{table}[h]
\centering
\begin{tabular}{|c|c|c|c|}
\hline
Variable & Pre-Election & Post-Election & Significance \\
\hline
Money Demand & 0.05 & 0.02 & 1% \\
\hline
Interest Rate Ratio & 0.06 & 0.03 & 5% \\
\hline
\end{tabular}
\caption{Results for Money Demand and Interest Rate Ratio}
\end{table}

We find that both output growth and the parameter for the relation of long-term to short-term rates show the expected signs. The former variable is marginally significant in most cases, the latter is highly significant at the 1 percent level in every case. However, as predicted by the argument made above, the correlation between the interest rate ratio and money demand seems to change during the election period. In fact, as $a_2 > |a_1|$ in the case of DI and DIII, the election effect is strong enough to change the sign of the aggregated effect of (changes in) $i^L_t / i_t$ on $\hat{m}_t$. The coefficients are significant at the 1 and 5 percent levels respectively. Only in the case of DII is $a_2$ just marginally significant and slightly smaller than $a_1$. Based on these results, we conclude that the evidence supports our hypothesis: the political business cycle observable in German monetary aggregates is due to demand rather than to supply factors. The

\textsuperscript{19} See Muscatelli and Hurn (1992) for a description of the procedure for quarterly data. Detailed results are available on request. Note that, while our results do not change much with a less sophisticated approach to seasonal integration, the chosen approach is appropriate for the data set at hand.
effect is also within the quantitative range of the political business cycle identified in the literature.  

4. Conclusions

There seems to be a paradox in the empirical literature on the German Bundesbank. On the one hand, Germany is often said to have one of the most independent and also one of the most successful central banks in the world. On the other hand, recent work on political business cycles shows that such a cycle exists in German monetary aggregates. One possible explanation for this contradiction is that politics rather than economics actually drove the Bundesbank. The bank might have misused its independence in order to support governments before elections. It is hard, however, to bring this hypothesis in line with the available evidence. The Bundesbank seemed to sometimes postpone interest rate rises until immediately after elections, but it did not cause the political business cycle in German monetary aggregates.

We argue (and show empirically) that the answer to the puzzle may lie instead in the uncertainty created by upcoming elections. If partisan preferences of governments introduce permanent differences in the conduct of fiscal policy or government pressure on the central bank, interest-rate forecasts extending into post-election periods depend on a weighted average of the inflation rates expected for all possible election results. As a consequence, financial investors trying to avoid this uncertainty trade longer term assets for shorter term assets. This, in turn, enlarges monetary aggregates because German money supply is sufficiently elastic. Contrary to the Bundesbank’s rhetorical commitment to a monetaristic policy rule, this is indeed the case: empirically, its behavior is best described as an interest rate policy rule that sets the short term interest rate to minimize deviations from equilibrium values of inflation and real growth. After the election, when the preferences of the new government are apparent, the demand process driving the money stock up is reversed. For an outside observer, however, the

---

20 Appendix 3 shows that the growth rate of real M3 increases by 0.1 percentage points within 18 months before elections. This is about the change implied by the estimated reaction of the (change in the) interest rate ratio on the growth rate of real M3 during this period.
demand-induced pattern caused by the uncertainty associated with elections and, possibly, partisan politics might look like a opportunistic political business cycle.

We conclude that our results are of potential interest with respect to the literature on central bank independence and political business cycles. The evidence supplied helps to disentangle the contradiction between the Bundesbank's reputation as one of the world's most independent and conservative central banks and the traces of straightforward opportunistic business cycles in German monetary aggregates.

Appendix 1

Following Clarida and Gertler (1997), our structural VAR model is given by

\[(A1) \quad y_t = Cy_t + \sum_{i=1,3,6,9,12} A_i y_{t-i} + e_t,\]

\[(A2) \quad y_t = (\hat{r}_t, \hat{y}_t, \hat{\pi}_t, \hat{s}_t, \hat{i}_t^{usa}, \hat{m}_t, \hat{i}_t, \hat{w}_t)^T,\]

where we include monthly observations on the following variables: commodity prices \((r)\), industrial production \((y)\), the consumer price level \((\pi)\), retail sales \((s)\), the US Federal Funds Rate \((i^{usa})\), the real money supply \(M3\) \((m)\), the German short term interest rate \((i)\), and the real D-Mark/Dollar exchange rate \((w)\).\(^{21}\) All variables except the interest rates enter the model in the form of annual growth rates, i.e. annual first differences of the original monthly series in logs.\(^{22}\) We included two cointegration relationships between retail sales/real money stock and production. The observation period is 1951:01 to 1996:05 (545 observations). The matrix \(C\) captures the contemporaneous interrelationship between the variables and has the form

\[(A3) \quad C = \begin{bmatrix} 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ c(1) & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\ c(2) & c(3) & 0 & 0 & 0 & 0 & 0 & 0 \\ c(4) & c(5) & c(6) & 0 & 0 & 0 & 0 \\ c(7) & c(8) & c(9) & c(10) & 0 & 0 & 0 \\ 0 & c(11) & 0 & 0 & 0 & 0 & c(12) & 0 \\ c(13) & 0 & 0 & 0 & 0 & c(14) & 0 & c(15) \\ c(16) & c(17) & c(18) & c(19) & c(20) & c(21) & c(22) & 0 \end{bmatrix}.\]

The estimation procedure has to steps: first, we estimate the reduced form of the structural VAR:

\[(A4) \quad y_t = \sum_{i=1,3,6,9,12} \frac{B_i}{[I-C]^{-1}A_i} y_{t-i} + \frac{u_t}{[I-C]^{-1}e_t},\]

\(^{21}\) The series are available through the Bundesbank directly or through a commercial provider. The Bundesbank codes are: \(r\) YU0514, \(y\) UU1133/UU11NA, \(\pi\) (consumer price index) UU0062, \(s\) UU2660, \(m\) (nominal, M3) TU0800 (before 1957:01 supplemented with data from the Monthly Reports of the Bundesbank), \(i\) SU0101 (1951:1 to 1954:3 approximated by the Bundesbank’s discount rate, 1954:3 to 1959:12 computed from the Bundesbank’s Monthly Reports), \(w\) (nominal) WU5409. The real money supply and the real exchange rate are computed by dividing the original series by \(\pi\). The federal funds rate (before 1954:7 approximated by the FED’s, NY, discount rate), \(i^{usa}\), has been obtained from the FED, NY. Results throughout the paper do not change much if we use M1 or M2 instead of M3.

\(^{22}\) Berger and Woitek (1995) show that the use of the annual growth rates of our monthly time series is indeed the proper way to remove the seasonal component in the data.
In the second step, we estimate the matrix \( C \) from the reduced form residuals \( \mathbf{u}_t \) by IV estimation (for details, see Clarida and Gertler (1997)). By premultiplying the matrices \( \mathbf{B}_i \) by \((\mathbf{I}-\mathbf{C})\), we obtain the original VAR matrices \( \mathbf{A}_i \).

As discussed in Section 2.1, we also introduce controls for the “hard” period of the Bretton Woods system when estimating the model. No matter the specific form of these controls, we find the expected results concerning the contemporaneous effects on the policy variables:

- The short term or day-to-day interest rate increases in response to increasing commodity prices, increasing money demand, and a depreciation of the real exchange rate. However, none of the coefficients is significant on conventional levels. This can be interpreted as implying that the Bundesbank reacts on the basis of the information available at the beginning of a given period rather than on contemporaneous information. This result is already incorporated in the model for the bank’s reaction function.
- Money demand depends significantly negatively on innovations in the day-to-day rate.
- An innovation in the funds rate leads to a significant depreciation of the real exchange rate, while an innovation in the day-to-day rate has the reverse effect.

The contemporaneous characteristics of the estimated extended model are quite similar to the ones obtained by Clarida and Gertler (1997) for the post-1973 subperiod. The same holds for the dynamic patterns of the model. As to the effects of monetary policy, we find that a rise in the day-to-day rate leads to a temporary decrease of production across all subperiods with the negative impact lagged about 6-12 months. A positive shock to the day-to-day rate leads to a temporary decrease in real monetary aggregates after a somewhat longer lag. As in Clarida and Gertler (1997), German consumer prices show signs of the so-called "price puzzle", i.e. inflation reacts positively to a rise in the short-term interest rate, even though the model includes commodity prices as suggested by Sims (1992). Since we cannot determine the lag structure based on this result, we apply the same lag structure for prices and for output. In general, our dynamic results are in line with what other researchers have found in similar approaches (see e.g., Taylor (1993a), Weber (1996), Leeper and Sims (1994)).

---

23 Experiments with other potential inflation predictors were also not successful.
24 We systematically experimented with alternative lag structures, having price effects leading or trailing output but found that results do not depend on the lag structure chosen.

</tbody>
</table>

Notes:

- The table shows that there is an increase (decrease) in real M3 significant at conventional levels about half a year before (about one year after) federal elections.
- M3 real are annual growth rates (annual first differences of the original series in logs).
- D_3/D_2/D_1 is 1 in the 18/12/6 months before an election and 0 otherwise; D3/D2/D1 is 1 in the 18/12/6 months after an election and 0 otherwise.
- The null-hypothesis of the Q-test ("The residuals are white noise") could not be rejected in any case. $R_{adj}^2$ is about 0.9 in all cases. Detailed results are available on request.

Estimation is by instrumental variables. The instruments are lagged values of the explanatory variables (lag 2), the political dummy and 5 lagged values of \( i_t \). \( R_{adj}^2 \) is about 0.9; The Box-Ljung statistic does not reject the hypothesis of white noise residuals up to a lag of 17 (5 percent significance level).
Table 3: The Political Business Cycle in $i_t/i$

<table>
<thead>

</tbody>
</table>

$R^2_{adj}$ is about 0.7; The Box-Ljung statistic does not reject the hypothesis of white noise residuals up to a lag of 20 (5 percent significance level). In order to adjust for the time dependent volatility of the interest rate ratio, we estimated equation (8) under the assumption that the ratio follows an ARCH-process.
